Abstract

This paper explores the situation when tenants in public houses, in a specific neighborhood, are given the legislated right to buy the houses they live in but can choose to remain in their houses and pay the regulated rent. This type of legislation has been passed in many European countries in the last 30–35 years (U.K. Housing Act 1980 is a leading example). The main objective with this type of legislation is to transfer the ownership of the houses from the public authority to the tenants. To achieve this goal, the selling prices of the public houses are typically heavily subsidized. The legislating body then faces a trade-off between achieving the goals of the legislation and allocating the houses efficiently. This paper investigates this specific trade-off and identifies an allocation rule that is individual rational, equilibrium selecting, and group non-manipulable in a restricted preference domain that contains “almost all” preference profiles. In this restricted domain, the identified rule is the equilibrium selecting rule that transfers the maximum number of ownerships from the public authority to the tenants. This rule is also weakly preferred to the current U.K. system by both the existing tenants and the public authority. Finally, a dynamic process that finds the outcome of the identified rule, in a finite number of steps, is provided.

1 Introduction

Public housing is a common form of housing tenure in which the property is owned by a local or central government authority. This type of tenure has traditionally referred to a situation where the central authority lets the right to occupy the units to tenants. In the last 30–35 years, however, many European countries have experienced important changes in their policies. In United Kingdom, for example, the “Right to Buy” was implemented in the U.K. Housing Act 1980. As indicated by its name, the legislation gave existing tenants the right to buy the houses they were living in (a tenant could, however, choose to remain in the house and pay the regulated rent).\(^1\) The U.K. Secretary of State for the Environment in 1979, Michael Heseltine, stated that the main motivation behind the Act was:

"... to give people what they wanted, and to reverse the trend of ever increasing dominance of the state over the life of the individual".\(^2\)

In other words, the main objective of the Act was to transfer the ownership of the houses from the local or central authority to the existing tenants. To cope with this objective, the Act also specified that tenants could buy the houses at prices significantly below the market price and that resale not is allowed within five years after purchasing the houses. In the latest update of the Act from 2012, this “discount” was specified to a maximum of £75000 or 60 percent of the house value (70 percent for an apartment) depending on which is lower.\(^3\) As can be expected, the result of the Act was that the proportion of public housing in United Kingdom fell from 31 percent in 1979 to 17 percent in 2010.\(^4\) Similar legislations, with similar effects, has been passed in several European countries, including Germany, Ireland, and Sweden, among others.

An important feature of the above type of legislation is that existing tenants always have the option to continue renting the houses at the regulated rents (“Right to Stay and Rent”). This option also highlights an important trade-off between allocative efficiency and achieving the objectives of the legislation when existing tenants cannot afford to buy the houses at the market prices (which is the typical case, and also the reason for discounting the sales prices of the houses in the first place). More precisely, if the discount is “large”, there will be allocation inefficiencies as there are buyers that are willing to buy the houses at the market prices. On the other hand, if the prices of the houses not are discounted at all (i.e., if market prices prevail), the existing tenants prefer to continue renting, and, in

\(^1\)In United Kingdom, local authorities have always had legal possibilities to sell public houses to tenants, but until the early 1970s such sales were extremely rare.

\(^4\)“Housing Europe Review 2012 – The nuts and bolts of European social housing systems”, European Federation of Public, Cooperative and Social Housing (Brussels).
this case, the legislation will not achieve what it was designed to do. This trade-off is also the starting point of this paper.

The formal model considered in this paper has its most direct application to the above type of housing market,\footnote{There are also other interpretations, e.g., a housing market where the owner of a house and the person living in the house coincides, and where a local or central government authority imposes taxes on trade of the houses.} and the main practical implication of the model is an extension of the U.K. Housing Act 1980 and its European equivalents. This extension generates a more efficient allocation of the houses among the tenants without compromising with the main aim of the legislation. The formal model considers a pre-specified geographic area, called a neighborhood, and all existing tenants in the neighborhood are, by the public authority, asked to report their preferences over pairs of houses and prices. Given these reports, an allocation rule, which can be interpreted as a direct auction mechanism, identifies equilibrium prices for the “internal market” which consists only of the set of neighboring houses and their tenants, given the prerequisite that a tenant can buy any house in the neighborhood, including the one that he currently is possessing, or continue renting the house he currently is occupying. In the model, the public authority defines a fixed lower bound for the equilibrium prices, i.e., reservation prices, and in case an existing tenant buys the particular house he currently is living in, the tenant pays only the reservation price. One can think of these reservation prices as exogenously given and specified in the law as explained in the above. Hence, the only significant difference between the U.K. Housing Act 1980, and its European equivalents, and the model considered in this paper is that we extend the situation from the case where only an existing tenant can buy the house that he currently is occupying to a situation where houses can be reallocated among all existing tenants in a neighborhood.

A few remarks about the interpretation of the model and its relation to the U.K. Housing Act 1980, and similar legislations, are in order here. First, as a tenant in our framework always can choose to continue renting the house they live in or to buy it at the reservation price, exactly as in the prevailing U.K. system, but have the opportunity to buy some other house in the neighborhood, all tenants are weakly better off in the considered model compared to the current U.K. system. Second, because all sold houses in the current U.K. system are sold at the reservation prices, but all sold houses in the considered model are sold at prices weakly higher than the reservation prices, the public authority is weakly better off in the considered model compared to the current U.K. system.\footnote{This argument is, of course, only valid if the houses that are sold in the current U.K. system also are sold in the considered model. This is always the case as later illustrated in Proposition 7.} Third, the extension of the current U.K. system, captured in the formal model, is realistic as “mutual exchange” between tenants already is allowed in many of the European countries with a legislated “Right to Buy” option, e.g., Ireland, Sweden, and United Kingdom.\footnote{Mutual exchange refers to a situation where two (or more) tenants in the public housing sector swap their houses when they rent their houses from a public authority. Typical requirements for a mutual exchange to take place are that none of the tenants included in the swap owes rent, is in the process of being evicted, and is moving to a home that the landlord believes is too big or small for their circumstances.}
considered model captures the idea that housing needs may change over time, e.g., a family gets more children or some children moves out. In such cases, a family may want to change house but not housing area. This is not allowed in the prevailing U.K. system as resale not is allowed within 5 years after purchasing the house.

To solve the above described house allocation problem, it is natural to search for a price mechanism that is individual rational, equilibrium selecting, and non-manipulable. This type of rule guarantees that no tenant can loose by participating, that no further rationing mechanism is needed, and that the reported information is reliable which means that the central authority can be certain that the houses are allocated to the tenants in the neighborhood who value them the most. Given the interest in these three specific axioms, the perhaps most natural candidate for an allocation rule is based on a “minimum equilibrium price vector” as this type of rule previously has been demonstrated to satisfy these specific axioms in a variety of different contexts, including, e.g., single-item auction environments (Vickrey, 1961), assignment markets (Demange and Gale, 1985), and housing markets with rent control (Andersson and Svensson, 2014). Another natural price mechanism for the above described housing market is an individual rational, equilibrium selecting, and “trade maximizing” rule. The latter axiom guarantees that the maximum number of houses are transferred to the tenants in equilibrium in perfect accordance with the U.K. Housing Act 1980 and its European equivalents.

Even if one would suspect that the above two rules always recommend the same selection as lower prices intuitively should increase trade, it turns out that this is generally not the case.\(^8\) In fact, it is not even clear what any of the above two rules recommend due to the non-uniqueness of a minimum equilibrium price vector and the non-uniqueness of an allocation that maximizes trade. The non-uniqueness property of the two rules is a direct consequence of the fact that agents can block the trade of a house through the “Right to Stay and Rent” option. The multiplicity of a minimum equilibrium price vector have the severe consequence that any allocation rule based on minimum equilibrium prices is manipulable in the full preference domain. Similarly, the multiplicity of an allocation that maximizes trade have the consequence that any allocation rule based on maximum trade is manipulable in the full preference domain. However, by considering the preference domain where no two houses are “connected by indifference”\(^9\), it turns out that a minimum equilibrium price vector is unique for each preference profile in the domain, and that it is possible to base an individual rational, equilibrium selecting, and group non-manipulable allocation rule on this unique price vector. This rule also turns out to be a maximum trade rule in the restricted domain, and it, therefore, guarantees that the maximum number of houses are transferred from the public authority to the tenants. The minimum price mechanism also recommends an outcome that is weakly preferred to the current U.K. system by both the existing tenants and the public authority.

\(^8\)These two rules make the same selection for any profile in the preference domain if and only if there are at most two houses in the neighborhood. See Proposition 2.

\(^9\)This type of domain restriction is very mild as “almost all” preference profiles are included in the reduced domain. See Andersson and Svensson (2014) for a thorough discussion of a similar domain restriction.
Because the minimum price mechanism satisfies several nice properties in the restricted preference domain, as explained in the above, it is natural to search for a dynamic price process that identifies the outcome of it. This is especially true if one is interested in implementing its outcome on an existing housing market. For this reason, this paper also provides a dynamic price process that always locates the minimum equilibrium price vector in a finite number of steps.

The main results of the paper is not only of interest because of their practical relevance, they also contribute to the existing matching literature in a deeper sense. More explicitly, and to the best of our knowledge, this paper is the first to provide an individual rational, equilibrium selecting, trade maximizing, and non-manipulable allocation rule for a housing market with initial endowments (initial ownership) where monetary transfers are allowed. We also remark that the main results presented in this paper are non-trivial extensions of similar and previously known results because most of the previous literature either consider the case with no initial endowments and where monetary transfers are allowed, or initial endowments but where monetary transfers not are allowed. In the following, we explain in more detail how the theoretical findings of this paper contributes to the existing and related literature.

The idea to use a minimum equilibrium price vector as a key ingredient in an individual rational, equilibrium selecting, and non-manipulable allocation rule was first advocated by Vickrey (1961) in his single-unit sealed-bid second-price auction. His principle was later generalized by Demange and Gale (1985) to the case where multiple heterogenous houses are to be sold. The main differences between this paper and the paper by Demange and Gale (1985) is that they consider a pure two-sided market in the sense that buyers cannot block sales. Hence, their model cannot handle the case with existing tenants or initial ownership, and, consequently, not the case when buyers can block the trade of a house through the “Right to Stay and Rent” option. However, both the allocation rule considered in this paper and the one in Demange and Gale (1985) share the property that the outcome of the rule is “envy-free” (Foley, 1967) in the sense that no agent wishes to swap consumption bundle with another agent once the houses are allocated and the prices are determined by the rule.\(^\text{10}\)

A model with existing tenants and prices is studied by Miyagawa (2001). In his setting, each tenant owns precisely one house and is a seller as well as a buyer, so money and houses are reallocated through a price mechanism exactly as in this paper. Unlike this paper (and, e.g., Vickrey, 1961; Demange and Gale, 1985), Miyagawa (2001) requires the mechanism to be “non-bossy” (Satterthwaite and Sonnenschein, 1981) which roughly means that no tenant can change the assignment for some other tenant without changing the assignment for himself. The assumption of non-bossiness has dramatic consequences on any non-manipulable allocation rule in this setting. Namely, any individual rational, non-bossy, and non-manipulable allocation rule is a fixed price mechanism. This also means that the

\(^{10}\)Equilibrium and no-envy has been investigated previously in a two-sided setup with indivisibilities by, e.g., Alkan, Demange, and Gale (1991), Gale (1984), Quinzii (1984), Svensson (1983), Sun and Yang (2003), and Tadenuma and Thomson (1991).
outcome of his fixed price mechanism typically is not envy-free. Because we do not require non-bossiness, our allocation rule is not a fixed price mechanism and it always selects an envy-free outcome.

Individual rational and non-manipulable mechanisms for housing markets with existing tenants has been considered previously in the literature also in the case when monetary transfers not are allowed. Most notably is the Shapley and Scarf (1974) Top-Trading Cycles Mechanism, further investigated by, e.g, Ma (1994) and Postlewaite, and Roth (1977,1982). This mechanism always selects an outcome in the core, and has later been generalized by Abdulkadiroğlu and Sönmez (1999) to allow for the case when there is a set of potential tenants that currently do not have a house. However, the allocation rules in these papers will, in similarity with Miyagawa (2001), not generally select an envy-free outcome, neither can they handle the case with monetary transfers.

Finally, a recent and intermediate proposal is due to Andersson and Svensson (2014) where houses are allocated among a set of potential tenants on a two-sided market where prices are bounded from above by price ceilings imposed by the government or a local administration. They define an individual rational, stable and group non-manipulable allocation rule that, in its two limiting cases, selects that same outcomes as the rule in Demange and Gale (1985) and the Deferred Acceptance Algorithm (Gale and Shapley, 1962). However, even if their mechanism is based on a minimal (rationing) equilibrium price vector, their allocation rule can neither handle existing tenants, nor will it generally select an envy-free outcome.

The remaining part of this paper is organized as follows. Section 2 introduces the formal model and some of the basic definitions that will be used throughout the paper. The allocation rules are introduced in Section 3 where also the main existence and non-manipulability results of the paper are stated. Section 4 provides a dynamic process that identifies the outcome of the considered allocation rule in a finite number of steps. Section 5 contains some concluding remarks. All proofs are relegated to the Appendix.

2 The Model and Basic Definitions

The agents and the houses are gathered in the finite sets \( A = \{1, \ldots, n\} \) and \( H = \{1, \ldots, n\} \), respectively, where \( n = |A| \) is a finite natural number. Note that the number of agents and houses coincide as we assume that there is an existing tenant in each house. Agent \( a \) is the existing tenant of house \( h \) if \( h = a \). It is often natural to assume that there are several owners of the houses, but since our results do not require this, it is assumed that there is a single owner of all houses.\(^{11}\) We also remark that the owner of the houses is not an existing tenant in the current interpretation of the model.\(^{12}\)

Each house \( h \in H \) have a price \( p_h \in \mathbb{R}_+ \). These prices are gathered in the price vector \( p \in \mathbb{R}^n_+ \) which is bounded from below by the reservation prices \( \underline{p} \in \mathbb{R}^n_+ \) of the owner. The

\(^{11}\)Our results extend with only a few notational modifications to the case with multiple owners.

\(^{12}\)It is, however, possible to allow for this case, see footnote 5.
reservation prices are arbitrary but fixed and define a feasible set of prices \( \Omega \) according to:

\[
\Omega = \{ p \in \mathbb{R}_+^n : p \geq \underline{p} \}.
\]

One can think of the reservation prices as exogenously given and specified in the law as explained in Section 1.

Agent \( a \in A \) can continue renting house \( h = a \) to the given fixed rent or buy the house he currently is living in at the owner’s reservation price \( p_a \). Agent \( a \) can also buy house \( h \neq a \) at price \( p_h \). For notational simplicity, and without loss of generality, the fixed rents will not be introduced in the formal framework. Formally, each agent \( a \in A \) consumes exactly one (consumption) bundle, \( x_a \), in his consumption set \( X_a = (H \times \mathbb{R}_+) \cup \{ a \} \) where:

\[
x_a = \begin{cases} 
a & \text{if agent } a \text{ continues to rent house } h = a, \\
a & \text{if agent } a \text{ buys house } h = a \text{ at price } p_a, \\
(h, p_h) & \text{if agent } a \text{ buys house } h \text{ at price } p_h. 
\end{cases}
\]

Note that \( x_a = a \) if agent \( a \) continue renting or buys the house he currently is living in. The agent’s choice between these two options does not affect the other agents. For technical reasons, an agent \( a \) can also buy his own house at the price \( p_a \), but that will not be the choice of a utility maximizing agent if \( p_a > p_a \). For simplicity, a bundle of type \( (h, p_h) \) will often be written as \( (h, p) \), i.e., \( (h, p) \equiv (h, p_h) \). It is then understood that \( (h, p) \) means house \( h \in H \) with price \( p_h \) at the price vector \( p \).

Each agent \( a \in A \) has preferences over bundles. These preferences are denoted by \( R_a \) and are represented by a complete preorder on \( X_a \). The strict and indifference relations are denoted by \( P_a \) and \( I_a \), respectively. Preferences are assumed to be strictly monotonic. This means that the agents strictly prefer a lower price to a higher price on any given house, i.e., \( (h, p_h)P_a(h', p_h) \) if \( p_h < p_h' \) for any agent \( a \in A \) and any house \( h \in H \). It is further assumed that each house in \( H \) is bounded desirable. This means that if the price of a house is “sufficiently high”, the agents will strictly prefer to keep the house they currently are living in rather than buying some other house, i.e., \( aP_a(h, p_h) \) for each agent \( a \in A \) and for each house \( h \in H \) for \( p_h \) “sufficiently high”. All preference relations \( R_a \) satisfying the above properties for agent \( a \in A \) are gathered in the set \( R_a \). A (preference) profile is a list \( R = (R_1, \ldots, R_n) \) of the agents’ preferences. This list belongs to the set \( \mathcal{R} = \mathcal{R}_1 \times \cdots \times \mathcal{R}_n \). We also adopt the notational convention of writing a profile \( R \in \mathcal{R} \) as \( R = (R_C, R_{-C}) \) for some nonempty subset \( C \subseteq A \).

A state is a triple \((\mu, \nu, p)\), where \( \mu : A \rightarrow H \) is a mapping assigning houses to the agents, \( \nu : A \rightarrow \{0, 1\} \) is an assignment indicating if an agent \( a \in A \) is renting, \( \nu_a = 0 \), or buying, \( \nu_a = 1 \), and \( p \in \mathbb{R}^n \) is a price vector. If agent \( a \in A \) is assigned house \( \mu_a \in H \) and \( \nu_a = 1 \), he pays:

\[
p_{\mu_a} = \begin{cases} 
p_{\mu_a} & \text{if } \mu_a \neq a, \\
p_a & \text{if } \mu_a = a.
\end{cases}
\]

The assignment function \( \mu \) is a bijection with the restriction \( \mu_a = a \) if \( \nu_a = 0 \). This means that an agent cannot rent a house that he currently not is living in. Agent \( a \) is also the
only agent that can buy house $h = a$ to the reservation price. We will use the simplified
notation $x = (\mu, \nu, p)$ for a state, where $x \in \Pi_{a \in A} X_a$ and $x_a = (\mu_a, p)$ if $\nu_a = 1$ and $\mu_a \neq a$, and $x_a = a$ if $\mu_a = a$ and $\nu_a \in \{0, 1\}$. Here it is understood that $\nu_a = 0$ only if $a \in P_a(x_a(h, p))$.

The norm $|\nu|$ of the assignment $\nu$ indicates the number of agents that are buying a
house at state $(\mu, \nu, p)$, and it is defined as $|\nu| = \Sigma_{a \in A} \nu_a$.

**Definition 1.** For a given profile $R \in \mathcal{R}$, a price vector $p \in \Omega$ is an *equilibrium price vector* if there is a state $x = (\mu, \nu, p)$ such that the following holds for all agents $a \in A$: (i) $x_a R_a a$, and (ii) $x_a R_a (h, p)$ for all $h \in H$. If, in addition, the norm of the assignment $\nu$ is maximal, the state $x$ is an *equilibrium state*.

A state is therefore an equilibrium state if any agent weakly prefers his bundle to the
house that he currently is renting (*individual rationality*) and to all other other houses at
the given prices, and, if, in addition, trade is maximal. The latter condition reflects the
fact that the owner of the houses prefers to sell the houses rather than keeping existing
tenants (recall from Section 1 that this is the main goal of U.K. Housing Act 1980 and
similar legislations). We also remark that any equilibrium state is *envy-free* (Foley, 1967)
in the sense that each agent weakly prefers his own bundle to the bundles assigned to the
other agents.\footnote{Formally, if $(h, p)_{P_a x_a}$ for some agent $a \in A$ at state $x = (\mu, \nu, p)$, agent $a$ is said to *envy* the agent $j \in A$ with $\mu_j = h$. If no agent $a \in A$ envies any agent $a' \in A$ at state $x = (\mu, \nu, p)$, the state $x$ is *envy-free*.}

For a given profile $R \in \mathcal{R}$, the set of equilibria is denoted by $\mathcal{E}_R$. Let also $\Pi_R$ be the
set of equilibrium prices at profile $R \in \mathcal{R}$, i.e.:

$$
\Pi_R = \{ p \in \mathbb{R}^n : (\mu, \nu, p) \in \mathcal{E}_R \text{ for some assignments } \mu \text{ and } \nu \}.
$$

An equilibrium price vector $p'$ is a *minimum* equilibrium price vector, at a given profile $R \in \mathcal{R}$, if $p' \in \Pi_R$, $p \leq p'$, and $p \in \Pi_R$ only if $p = p'$.

Finally, a state $(\mu, \nu, p)$ is a *maximum trade equilibrium*, at a given profile $R \in \mathcal{R}$, if
$(\mu, \nu, p) \in \mathcal{E}_R$ and $|\nu| \geq |\nu'|$ for all $(\mu', \nu', p') \in \mathcal{E}_R$.

### 3 Manipulability and Non-Manipulability Results

As already explained in Section 1, it is natural to let a minimum equilibrium price vector
be a key ingredient in an allocation rule for the considered house allocation problem as
this type of rule previously has been demonstrated to be individual rational, equilibrium
selecting, and non-manipulable in various economic environments. Another natural price
mechanism is based on individual rationality, equilibrium selection, and maximal trade.
Here, the latter axiom guarantees that the rule maximizes the number traded houses, i.e.,
that it achieves the objectives of the U.K. Housing Act 1980 and similar legislations. These
two rules are next formally defined.

Consider the preference domain $\mathcal{R}^* \subseteq \mathcal{R}$, and let $\mathcal{E}^* = \bigcup_{R \in \mathcal{R}^*} \mathcal{E}_R$. A *rule* is a function $f : \mathcal{R}^* \to \mathcal{E}^*$ where, for each profile $R \in \mathcal{R}^*$, the rule $f$ selects an equilibrium state
A rule is called a *minimum price mechanism* if it, for each profile \( R \in \mathcal{R}^* \), selects an equilibrium state \((\mu, \nu, p) \in \mathcal{E}_R\) where \( p \) is a minimum equilibrium price vector. A rule is called a *maximum trade rule* if it, for each profile \( R \in \mathcal{R}^* \), selects an equilibrium state \((\mu, \nu, p) \in \mathcal{E}_R\) that, in addition, is a maximum trade equilibrium.

To be certain that the above two rules are well-defined, we need to establish that the equilibrium set \( \mathcal{E}_R \) is nonempty for all profiles in \( \mathcal{R} \) because in this case, \( \Pi_R \) will also be nonempty for all profiles in \( \mathcal{R} \) by definition. The existence of a minimum equilibrium price vector then follows directly as the set of equilibrium prices is bounded from below by \( p \) and closed since preferences are continuous, and the existence of a maximum trade equilibrium follows by the non-emptiness of the equilibrium set.

**Proposition 1.** The set of equilibria \( \mathcal{E}_R \) is nonempty for each profile \( R \in \mathcal{R} \) and for any vector of reservation prices \( p \).

We will next, in a series of examples and propositions, investigate the similarities and differences between the above defined rules. The first example demonstrates that the selection of a minimum price mechanism and the selection of a maximum trade rule need not be identical in the full preference domain \( \mathcal{R} \). This result is a bit counterintuitive as one would suspect that these rules always recommend the same selection as lower prices intuitively should increase trade.

**Example 1.** Let \( A = \{1, 2, 3\} \) and \( H = \{1, 2, 3\} \) be the sets of agents and houses, respectively, where agent \( a \in A \) is the existing tenant of house \( h = a \). Let also \( p = (0, 0, 0) \). For each agent \( a \in A \), preferences over bundles \((h, p)\) are represented by a quasi-linear utility function \( u_{ah}(p) = v_{ah} - p_h \) where the values \( v_{ah} \) are represented by real numbers. Let the utility for agent \( a \in A \) of renting house \( h = a \) formally be represented by \( v_{a0} \), and:

\[
V = (v_{ah}) = \begin{pmatrix}
-2 & -2 & 3 & 2 \\
-2 & 1 & 1 & -2 \\
0 & 0 & 0 & -2
\end{pmatrix}.
\]

In this case, \( p = (0, 0, 0) \) is the unique minimum equilibrium price vector as \( x = (\mu, \nu, p) \) is an equilibrium state for \( \mu = (2, 1, 3) \) and \( \nu = (1, 1, 0) \). Note next that \( x \) is the only possible selection of a minimum price mechanism and, moreover, that \( x' = (\mu', \nu', p') \) is a possible selection of a maximum trade rule for \( \mu' = (3, 2, 1) \), \( \nu' = (1, 1, 1) \), and \( p' = (0, 1, 0) \). Hence, \(|\nu'| > |\nu|\) which demonstrates that a minimum price mechanism and a maximum trade rule need not make identical selections.

The observation from Example 1 is in fact more general than in appears. This is revealed in the following proposition.

**Proposition 2.** Let \( f \) be a minimum price mechanism with domain \( \mathcal{R} \). Then \( f \) is a maximum trade rule if and only if \( 1 \leq |A| \leq 2 \).

We also remark that a maximum trade rule need not be a minimum price mechanism for any \( |A| \geq 1 \) on the domain \( \mathcal{R} \). This can intuitively be understood by considering the special
case when all agents always strictly prefer to buy the house they currently are living in to renting it or to buying some other house, i.e., \((a, p) \mathcal{P} a\) and \((a, p) \mathcal{P} (h, p_h)\) for all \(a \in A\), all \(h \neq a\), and all \(p \geq p\). In this case, a minimum price mechanism will have maximal trade, as all agents buy the house they are living in, and the unique minimum equilibrium price vector is given by \(p = (p_1, \ldots, p_n)\). In this special case, however, maximal trade will be the outcome of any equilibrium selecting rule for any price vector \(p \geq p\), i.e., a maximum trade rule need not necessarily recommend the same state as a minimum price mechanism as the price vector may differ between the two rules.

The following example demonstrates that neither a minimum price mechanism nor a maximum trade rule need to make a unique selection on the full preference domain \(\mathcal{R}\).

**Example 2.** Let \(A = \{1, 2, 3, 4\}\) and \(H = \{1, 2, 3, 4\}\) be the sets of agents and houses, respectively. As in Example 1, it is assumed that preferences are represented by quasi-linear utility functions. Let also:

\[
V = (v_{ah}) = \begin{pmatrix}
0 & 0 & -2 & 0 & -2 \\
-2 & 0 & 0 & -2 \\
0 & 2 & -2 & -2 & 1 \\
0 & -2 & 2 & -2 & 1
\end{pmatrix}.
\]

In this case, both \(p' = (1, 0, 0, 0)\) and \(p'' = (0, 1, 0, 0)\) are minimum equilibrium price vectors. This follows since both \(x' = (\mu', \nu', p')\) and \(x'' = (\mu'', \nu'', p'')\) are equilibrium states for \(\mu' = (1, 3, 4, 2), \nu' = (1, 1, 1, 1), \mu'' = (3, 2, 1, 4), \) and \(\nu'' = (1, 1, 1, 1)\). Note also that trade is maximized at states \(x'\) and \(x''\) since \(|\nu'| = |\nu''| = |A|\). □

The multiplicity of a minimum equilibrium price vector and a maximum trade equilibrium is a direct consequence of the fact that agents can block the trade of a house through the “Right to Stay and Rent” option. It also have the severe consequence that any minimum price mechanism and any maximum trade rule is manipulable on the full preference domain, at least if there are more than three houses on the housing market. The following notion of group manipulability and group non-manipulability is employed.

**Definition 2.** A rule \(f\) with domain \(\mathcal{R}^* \subseteq \mathcal{R}\) is **manipulable** at a profile \(R \in \mathcal{R}^*\) by a nonempty group of agents \(C \subseteq A\) if there is a profile \(R' = (R'_C, R_{-C}) \in \mathcal{R}^*\), and two states \(f(R) = x = (\mu, \nu, p)\) and \(f(R'_C, R_{-C}) = x' = (\mu', \nu', p')\) such that \(x'_a \mathcal{P} a x_a\) for all \(a \in C\).

If the rule \(f\) is not manipulable by any group \(C \subseteq A\) at any profile \(R \in \mathcal{R}^*\), it is **group non-manipulable**.

**Proposition 3.** A minimum price mechanism \(f\) is non-manipulable on the domain \(\mathcal{R}\) if and only if \(1 \leq |A| \leq 3\).

The result in Proposition 3 does not generally carry over to maximum trade rules. It is indeed true that any maximum trade rule can be manipulated if \(|A| > 3\) (see Proposition 4) but due to the large number of possible maximum trade rules, it depends on the specific maximum trade rule if it is manipulable or not in the interval \(1 \leq |A| \leq 3\). For example,
as a minimum price mechanism is a maximum trade rule in the interval $1 \leq |A| \leq 2$, by Proposition 2, it follows from Proposition 3 that a maximum trade rule that, in addition, is a minimum price mechanism is non-manipulable if $1 \leq |A| \leq 2$. On the other hand, a maximum trade rule that avoids to make the same selection as a minimum price mechanism for any profile in $\mathcal{R}$ whenever possible is non-manipulable on the domain $\mathcal{R}$ if and only if $|A| = 1$.\(^{14}\)

**Proposition 4.** A maximum trade rule $f$ is manipulable on the domain $\mathcal{R}$ if $|A| > 3$.

The implication from Propositions 3 and 4 is that if one searches for non-manipulable rules on the full preference domain, one cannot search in the class of minimum price mechanisms or the class of maximum trade rules, at least, if one is interested in housing markets containing more than three houses. Of course, there are non-manipulable rules also on the full preference domain, e.g., a rule which, for any profile, sets prices “sufficiently high” so that all agents prefer either renting or buying the house they currently occupy. As this rule always recommends an identical outcome as the rule which currently is used in United Kingdom, it will not be of any interest to a public authority that aims to transfer more houses to tenants compared to the prevailing U.K. system.

In the following, we will demonstrate that by excluding some profiles from the domain $\mathcal{R}$ and instead consider the reduced preference domain $\tilde{\mathcal{R}} \subset \mathcal{R}$ where no two houses are “connected by indifference” at any price vector $p \in \Omega$, a minimum equilibrium price vector is unique for all profiles in the reduced domain, and that this price vector is a key ingredient in an individual rational, equilibrium selecting, and group non-manipulable rule, which, in addition, maximizes trade.

**Definition 3.** For a given profile $R \in \mathcal{R}$, two houses, $h$ and $h'$, in $H$ are **connected by indifference** if there is a price vector $p \in \Omega$, a sequence of distinct agents $(a_1, \ldots, a_q)$, and a sequence of distinct houses $(h_1, \ldots, h_{q+1})$ for $q \geq 1$ such that:

(i) $h = h_1 = a_1$, and $h' = h_{q+1} = a_q$,
(ii) $a_1I_{a_1}(h_2, p)$, and $a_qI_{a_q}(h_q, p)$,
(iii) $(h_j, p)I_{a_j}(h_{j+1}, p)$ for $2 \leq j \leq q - 1$ if $q > 2$.

The subset of $\mathcal{R}$ where no two houses are connected by indifference is denoted by $\tilde{\mathcal{R}}$.

\(^{11}\)The interested reader may consult the following example which is the key in a formal proof. Suppose, as in Example 1, that preferences are represented by quasi-linear utility functions, and that $A = H = \{1, 2\}$, $v_{10} = v_{11} = v_{20} = -2$, $v_{12} = 0$, $v_{21} = 1$, and $v_{22} = 0$. In this case, a maximum trade rule that do not make the same selection as a minimum price mechanism (whenever possible) will select the state $x = (\mu, \nu, p)$ where $\mu = (2, 1)$, $\nu = (1, 1)$, and $p = (\alpha, 0)$ for some $0 < \alpha \leq 1$. However, if agent 2 misrepresents and instead reports $v_{21} = 0$, agent 2 will still be assigned house 1 but at price 0. Hence, the gain by misrepresenting is $\alpha > 0$. \(^{11}\)
We remark that the above type of domain restriction contains “almost all” preference profiles. In fact, one can argue that the restriction of profiles to $\tilde{R} \subset R$ is an assumption of the same character as assuming strict preferences in the absence of monetary transfers, as, e.g., Abdulkadiroğlu and Sönmez (1999), Gale and Shapley (1962), and Ma (1994) among others, as also this assumption is mild if preferences are chosen randomly since the probability of an indifference then is zero. The following example illustrates a natural preference domain satisfying Definition 3.

Example 3. Consider the domain $\hat{R} \subset R$ where “indifference with the endowment” is excluded, i.e., $R \in \hat{R}$ if and only if either $aP_a(h, p_h)$ or $(h, p_h)P_a a$ for all $a \in A$ and all $(h, p_h)$. Exclusion of indifference with the endowment arises naturally when agents have a “status-quo bias” meaning that once an agent is indifferent between keeping the house he currently is living or buying some other house, the agent keeps his original house. Assumptions with a similar meaning has previously been made by, e.g., Sönmez (1999, Assumption A) in a generalized indivisible goods allocation problem, and by Erdil and Ergin (2006, NI∅ assumption) in a two-sided matching model without side payments. □

The first main result of the paper demonstrates that the set of equilibrium prices $\Pi_R$ has a unique minimum equilibrium price vector at any profile $R \in \tilde{R}$. This result also offers the explanation to the fact that there are two minimum equilibrium price vectors in Example 2. More precisely, houses $h = 1$ and $h' = 3$ are connected by indifference at prices $p' = (1, 0, 0, 0)$. To see this, consider agents 1 and 2 and the sequence of houses $(1, 3, 2)$. In this case, $q = 2$, $a_1 = 1$, $a_2 = a_q = 2$, $1I_1(3, 0)$, and $2I_2(3, 0)$ so all conditions of Definition 3 are satisfied (note that the last condition in the definition is irrelevant because $q = 2$), i.e., houses $h = 1$ and $h' = 3$ are connected by indifference at prices $p' = (1, 0, 0, 0)$.

Theorem 1. There is a unique minimum equilibrium price vector $p^* \in \Pi_R$ for each profile $R \in \tilde{R}$.

From Theorem 1, it is clear that the non-uniqueness problem, previously illustrated in Example 2, not is a problem on the restricted domain $\tilde{R}$. What may not be so obvious, in the light of Proposition 2, is that a minimum price mechanism always is a maximum trade rule on the restricted domain $\tilde{R}$.

Proposition 5. Let $f$ be a minimum price mechanism with domain $\tilde{R}$. Then $f$ is a maximum trade rule.

---

15 Informally, this can be understood by considering any profile $R \in R$, and any sequence of distinct agents $(a_1, \ldots, a_q)$ and any sequence of distinct houses $(h_1, \ldots, h_{q+1})$ with $h_1 = a_1$ and $h_{q+1} = a_q$. Suppose now that $a_1I_{a_1}(h_2, p)$ and $(h_j, p)I_{a_j}(h_{j+1}, p)$ for $2 \leq j \leq q - 1$. In this case, $p_{h_2}$ will be uniquely determined by continuity and monotonicity of the preferences. However, if preferences are chosen randomly, the probability is zero that $a_qI_{a_q}(h_q, p)$, i.e., that houses $h$ and $h'$ are connected by indifference. Hence, very few profiles are excluded in $\tilde{R}$ compared to $R$. See Andersson and Svensson (2014) for a thorough analysis of a similar domain restriction.

16 For technical purposes, we also need to assume that the set $\{p_h \in \mathbb{R} : (h, p_h)R_h a\}$ is closed for all $h \in H$. This assumption guarantees that for a decreasing convergent equilibrium price sequence, the assignment converges as well.
The last result of this section demonstrates that a minimum price mechanism, defined on the domain $\tilde{R} \subset R$, is group non-manipulable for all profiles in $\tilde{R}$. Note also that this mechanism always selects an individual rational equilibrium outcome that maximizes trade at each profile in $\tilde{R}$ by the definition of the rule and Proposition 5.

**Theorem 2.** Let $f$ be a minimum price mechanism with domain $\tilde{R}$. Then $f$ is group non-manipulable.

### 4 A Dynamic Price Process

This section provides a dynamic process for identifying a minimum equilibrium price vector in a finite number of steps. As an arbitrary but fixed profile $R \in R$ is considered throughout the section, we will for notational simplicity drop the profile notation $R$ in the equilibrium sets $E_R$ and $\Pi_R$, and instead write $E$ and $\Pi$, respectively.

The key in the dynamic process a sequence of minimum equilibrium price vectors $(p^1, \ldots, p^T)$ consistent with a sequence of fixed assignments $(\nu^1, \ldots, \nu^T)$. This type of sequence is called a “Dutch price sequence”, and to define it in more detail, some additional notation needs to be introduced. For this purpose, consider a fixed assignment $\nu$ (i.e., an assignment where, for each agent, is it exogenously given whether or not they rent a house), and let $\Pi^\nu$ be the set of equilibrium prices consistent with the fixed assignment $\nu$. Such a set of equilibrium prices is called a price regime. Formally, for any fixed assignment $\nu$, a set $\Pi^\nu \subset \Pi$ is defined to be a price regime if:

$$\Pi^\nu = \{p \in \Omega : \text{there is an assignment } \mu \text{ such that } p \in \Pi \text{ for } x = (\mu, \nu, p)\}.$$  

For each assignment $\nu$, the price regime $\Pi^\nu$ is a semi-lattice that is closed and bounded below and, hence, has a unique minimum equilibrium price vector $p^{\nu^*} \in \Pi^\nu$. Let $x = (\mu, \nu, p) \in E$ be an equilibrium state and define a price function $\pi : E \to \Omega$ according to $\pi(x) = p^{\nu^*}$. Hence, $\pi(x)$ is the unique minimum equilibrium price in the price regime defined by the assignment $\nu$ at the state $x$. Further, define a correspondence $\xi$ from minimum price vectors $p^{\nu^*}$ to equilibrium states according to:

$$\xi(p^{\nu^*}) = \{x' \in E : x' = (\mu', \nu', p^{\nu^*}) \text{ for some assignments } \mu' \text{ and } \nu'\}.$$  

**Definition 4.** A (possibly infinite) price sequence $(p^t)_{t=1}^T$ of equilibrium prices is a Dutch price sequence if:

(i) $p^1 = \pi(x^0)$ for some equilibrium state $x^0 = (\mu^0, \nu^0, p^0)$ with $\mu_a^0 = a$ for all $a \in A$,

(ii) there is a supporting sequence $(x^t)_{t=1}^T$ of equilibrium states such that for some $x^t \in \xi(p^t)$, it holds that $p^{t+1} = \pi(x^t)$,

(iii) $p^T = \pi(x^{T-1})$ and for each $x \in \xi(p^T)$ and $p = \pi(x)$, it holds that $p = p^T$ whenever the price sequence $(p^t)_{t=1}^T$ ends at a finite step $T$.
To get a better understanding of a Dutch price sequence, consider Figure 1 and the price vector $p^0$ where all agents prefer to keep the house they currently are living in by either renting or buying it. Such a price vector always exists as this always will be the case for “sufficiently high” prices. But then there is an equilibrium state $x^0 = (\mu^0, \nu^0, p^0)$ as defined in Definition 4(i). Recall next that for the price vector $p^0$, there is a corresponding price regime $\Pi^{p^0}$ with a unique minimum equilibrium price vector. This vector is denoted by $p^1 = \pi(x^0)$. Now, given prices $p^1$, there is a corresponding supporting equilibrium state $x^1 = (\mu^1, \nu^1, p^1)$. Note that this state is not necessarily unique. In the left panel of Figure 1, for example, there are two supporting equilibrium states, $\hat{x}^1 = (\ldots, \hat{x}_i^1, \hat{x}_j^1, \ldots)$ and $\tilde{x}^1 = (\ldots, \tilde{x}_i^1, \tilde{x}_j^1, \ldots)$, with corresponding minimum equilibrium price vectors $\hat{p}^2 = \pi(\hat{x}^1)$ and $\tilde{p}^2 = \pi(\tilde{x}^1)$. Any of these price vectors may be chosen and the arguments can be repeated in the exact same fashion. In this way, a Dutch price sequence, $(p^1, p^2, \ldots, p^t, \ldots)$, as illustrated in the right panel of Figure 1, will be obtained (disregard the dotted path that connects the price vector in the Dutch price sequence for the moment, it will be explained later in this section). What may not be so obvious is that such a sequence always contains a finite number of equilibrium price vectors. This is demonstrated in the following proposition.\[17\]

**Proposition 6.** For any given profile $R \in \mathcal{R}$, a Dutch price sequence $(p^t)_{t=1}^T$ contains only a finite number of price vectors, i.e., $T < \infty$.

We next remark that any Dutch price sequence satisfies two important properties. First, $p^{t+1} \leq p^t$ and $p^{t+1} \neq p^t$ for any $t$ in the sequence. This follows since $p^t \in \Pi^{\nu^t}$, and $p^{t+1}$ is the minimum price vector in the price regime $\Pi^{\nu^t}$. Second, the norm of the assignment $\nu$ is weakly increasing in the sequence, i.e., if the number of agents that are buying houses at $t$ and $t+1$ are denoted by $|\nu^t|$ with $|\nu^{t+1}|$, respectively, it must be the case that $|\nu^{t+1}| \geq |\nu^t|$. This follows since, at an equilibrium state, the number of buying agents is always maximal.

\[17\]Note also that the above arguments can be use to construct a Dutch price sequence for any profile in $\mathcal{R}$ and any vector of reservation prices. Hence, there always exists a Dutch price sequence.
at the given price vector. A change from the price regime $\Pi^{\nu_t}$ to the price regime $\Pi^{\nu_{t+1}}$ entails a change of agents that are buying, but the number of buying agents cannot decrease.

As is clear from the above description, there may be several Dutch price sequences for a given profile $\mathcal{R}$ and a given initial start prices $p^0$ (see, e.g., the left panel of Figure 1). However, if the profile is selected from the domain $\tilde{\mathcal{R}}$ where no two houses are “connected by indifference”, there will be exactly one Dutch price sequence for the given profile. Even more strikingly, the end point of the sequence must be the, by Theorem 1, unique minimum equilibrium price vector $p^* \in \Pi$ for the given profile $R \in \tilde{\mathcal{R}}$. Both these results are formally stated in the last theorem of the paper.

**Theorem 3.** For any given profile $R \in \tilde{\mathcal{R}}$, a Dutch price sequence $(p^t)_{t=1}^T$ is unique, and $p^T$ is the unique minimum equilibrium price vector in $\Pi_R$.

A final observation is that the price vectors in the a unique Dutch price sequence can be identified and connected by applying the “Vickrey-Dutch Auction” (Mishra and Parkes, 2009) in the case when preferences are quasi-linear, and by the Dutch counterpart of the “SA Auction” in Morimotoy and Serizawa (2014) in the more general case. More explicitly, for any given profile in $\tilde{\mathcal{R}}$, the unique minimum equilibrium price vector can be obtained by adopting the following dynamic price process.

**The Dynamic Price Process.** Initialize the price vector to “sufficiently high” prices $p^0$ in the sense that each agent prefers not to buy any house they currently are not living in, i.e., $x^0_a = a$ for all $a \in A$. Then for each Step $t := 0, \ldots, T$:

- **Step $t$.** For the given $p^t$ and the fixed assignment $\nu^t$, identify the unique minimum equilibrium price vector $p^{t+1} = \pi(x^t)$ in the corresponding price regime $\Pi^{\nu^t}$. If $p^{t+1} = p^t$, stop. Otherwise set $t := t + 1$ and continue. □

If one adopts the Vickrey-Dutch Auction or the Dutch counterpart of the SA Auction to identify the unique minimum equilibrium price vector in the corresponding price regime $\Pi^\nu$, it follows directly from the above findings and the convergence results in Mishra and Parkes (2009, Theorem 2), and Morimotoy and Serizawa (2014, Proposition 5.1) that the above process is well-defined and that it will converge to the unique minimum equilibrium price vector, for the given profile $R \in \tilde{\mathcal{R}}$, in a finite number of steps. In the right panel of Figure 1, the above procedure will generate the finite path which is represented by the dotted line.

### 5 Concluding Remarks

In the special case of the formal model when the set $A$ contains exactly one agent, the situation in which the U.K. Housing Act 1980 and its European equivalents are applicable will be fully reflected in the formal framework. That is, the single tenant is given a take-it-or-leave-it offer either to buy the house at a fixed and discounted price, or to continue
renting the house. If the agent would report his preferences to the local or central administration, the minimum equilibrium price mechanism would recommend the real-world outcome. Hence, the model considered in this paper can be seen as a representation of the public housing market in United Kingdom today where each tenant is regarded as a “separate housing market”. This situation will most likely cause allocative inefficiencies as the houses not necessarily are allocated to the tenants who value them the most. The compromise proposed in this paper is to merge some of these “separate housing markets” into a new and larger housing market (e.g., all houses in a specific neighborhood). In this way, the houses can be more efficiently allocated among the tenants but the tenants are, at the same time, protected against “too high” living costs.

As a tenant always have the option to buy the particular house that he is living in at the fixed reservation price or to continue renting it at the regulated rent, in the formal framework, it is clear that all agents weakly prefer the outcome of the investigated rule to the prevailing U.K. system. In fact, also the public authority weakly prefers the outcome of the minimum equilibrium price mechanism to the prevailing U.K. system as the revenue from the sales always is weakly higher in the suggested rule. This result is formally stated in the last proposition of the paper.

**Proposition 7.** For any profile $R \in \mathcal{R}$, the minimum price mechanism generates a weakly higher revenue to the public authority compared to the current U.K. system.

We have left a number of interesting research questions for future research, and we believe that two of them stand out more than the others. First, is the domain where no two houses are “connected by indifference” at any price vector, the maximal domain under which a minimum price mechanism is non-manipulable? Second, is the minimum price mechanism the only individual rational, equilibrium selecting, trade maximizing, and non-manipulable rule on the domain $\tilde{\mathcal{R}}$? Currently, we do not have an answer to these two questions but it would be interesting to know them, especially since the results of this paper have some very relevant policy implications.

### Appendix: Proofs

This Appendix contains the proofs of all results in the paper. It also contains some additional lemmas, definitions, and concepts. All results are proved in the same order as they are presented in the main text of the paper, except the proof of Proposition 3 which is proved directly after Theorem 2.

**Proposition 1.** The set of equilibria $\mathcal{E}_R$ is nonempty for each profile $R \in \mathcal{R}$ and for any vector of reservation prices $p$.

**Proof.** Since each house is bounded desirable for each agent $a \in A$ at each profile $R \in \mathcal{R}$, by assumption, there is a price vector $\overline{p} > p$ such that $aP_a(h, \overline{p})$ for all $a \in A$ and all $h \in H$. But then, $x = (\mu, \nu, \overline{p})$ constitutes an equilibrium state if $\mu_a = a$ for all $a \in A$, $\nu_a = 1$ if
(a, p_\alpha)|_R a, and v_\alpha = 0 if aP_\alpha(a, p_\alpha). Hence, x \in \mathcal{E}_R, and, consequently, \mathcal{E}_R \neq \emptyset for each profile R \in \mathcal{R}.

**Proposition 2.** Let f be a minimum price mechanism with domain \mathcal{R}. Then f is a maximum trade rule if and only if 1 \leq |A| \leq 2.

**Proof.** We first prove that f is a maximum trade rule if 1 \leq |A| \leq 2. For |A| = 1, this follows directly as the single agent is given a take-it-or-leave-it offer to either buy the house at price p_{\alpha|_R} or to continue renting it, and the fact that the agent will continue to rent only if 1P_1(1, p_{\alpha|_R}). Suppose now that |A| = 2 but that f is not a maximum trade rule on the domain \mathcal{R}. This means that there exists a profile R \in \mathcal{R} and two states, x = (\mu, \nu, p) \in \mathcal{E}_R and x' = (\mu', \nu', p') \in \mathcal{E}_R, where the former state is selected by a minimum price mechanism and the latter by a maximum trade rule and |\nu| < |\nu'|. Because |\nu'| > |\nu|, there must be an agent a_l \in A with \mu_{a_l} = a_l, \nu_{a_l} = 0, and \nu'_{a_l} = 1. Consequently, \mu_{a_l} = a_l, \mu_{a_k} = a_k, \mu'_{a_l} = a_k and \mu'_{a_k} = a_l for l \neq k as |A| = 2. Note next that x_{a_l}R_{a_l}x_{a_k} and x_{a_k}R_{a_k}x_{a_l} as x is an equilibrium state. Because \mu_{a_j} = a_j for j = 1, 2, it must be the case that p_{\mu_{x_{a_j}}} \leq p'_{\mu_{x_{a_j}}} for j = 1, 2 otherwise x' cannot be an equilibrium state. Now, p_{\mu_{x_{a_j}}} < p'_{\mu_{x_{a_j}}} for some j contradicts that p is a minimum equilibrium price vector in \Pi_R. Hence, p_{\mu_{x_{a_j}}} = p'_{\mu_{x_{a_j}}} for j = 1, 2, and, consequently, x_{a_l}I_{a_l}x_{a_k} and x_{a_k}I_{a_k}x_{a_l} as x' is an equilibrium state. But then x'' = (\mu'', \nu'', p'') = (\mu', \nu', p) is an equilibrium state at the minimum equilibrium price vector p with |\nu''| > |\nu| contradicting that the norm |\nu| is maximal at state x. Hence, state x cannot be an equilibrium.

The proof that f is a maximum trade rule on the domain \mathcal{R} only if 1 \leq |A| \leq 2 follows directly from Example 1. To see this, note that in order to prove the result, it suffices to find a profile R \in \mathcal{R} for an arbitrary |A| \geq 3 where the rule can be manipulated by some agent. Consider now Example 1, and suppose that we add an arbitrary but finite number of agents to the set A = \{1, 2, 3\}, and that v_{j0} = 0 and v_{jk} = -2 for j = 4, \ldots, n, and all k \in A^* where A^* = \{1, 2, 3, 4, \ldots, n\}. Suppose, in addition, that v_{jk} = -2 for j = 1, 2, 3 and k = 4, \ldots, n. The added agents will always rent the house they currently live in and will not affect the outcome of the rule f for agents 1, 2, and 3. Because Example 1 demonstrates that a minimum price mechanism need not make an identical selection as a maximum trade rule when |A| = 3, the result will then carry of to the case when |A| \geq 3. \n
**Proposition 4.** A maximum trade rule f is manipulable on the domain \mathcal{R} if |A| > 3.

**Proof.** We will prove the proposition by identifying a profile R \in \mathcal{R} where some agent can manipulate the outcome of an arbitrary maximum trade rule f when |A| > 3. Using the same arguments as in the proof of Proposition 2, it is sufficient to demonstrate the result for |A| = 4. As in Example 1, let preferences be represented by quasi-linear utility functions where:

\[
V = (v_{ah}) = \begin{pmatrix}
0 & 0 & -2 & 0 & -2 \\
0 & -2 & -2 & 0 & -2 \\
0 & -2 & -2 & 1 & -2 \\
0 & 2 & -2 & -2 & 1 \\
-2 & 2 & -2 & 1 & 0
\end{pmatrix}.
\]
In the remaining part of the proof, we let the profile \( R \in \mathcal{R} \) denote the preferences that are represented by the above values. Note first that \( x = (\mu, \nu, p) \) is an equilibrium state for \( \mu = (1, 3, 4, 2), \nu = (1, 1, 1, 1) \), and \( p = (1, 0, 0, 0) \). Note, in particular, that \( |\nu| = 4 \). This also means that any selection \( x' = (\mu', \nu', p') \) of a maximum trade rule \( f \) at profile \( R \) must have the property that \( |\nu'| = 4 \). But then it must also be the case that \( \mu'_2 = 3 \) and \( p'_3 = 0 \) at any selection \( x' \) of a maximum trade rule. This follows because if \( \mu'_2 \neq 3 \), then it must be the case that \( \mu'_2 = 2 \) and \( \nu'_2 = 0 \) otherwise agent 2 will envy the agent \( a \) with \( \mu'_a = 2 \) at any feasible price vector. This contradicts that \( x' \) is an equilibrium. But \( \mu'_2 = 2 \) and \( \nu'_2 = 0 \) contradicts that \( x' \) is selected by a maximum trade rule at profile \( R \) as this implies that \( |\nu'| < 4 \). Hence, \( \mu'_2 = 3 \) and \( p'_3 = 0 \). By using similar arguments, it is clear that \( \mu'_1 = 1 \) and \( \nu'_1 = 1 \). As a consequence, \( \mu'_3 = 4, \nu'_3 = 1, p'_1 - p'_4 \geq 1 \), and \( p'_4 = 0 \leq p'_3 \leq 1 \). But if \( \mu'_3 = 4 \) and \( 0 \leq p'_4 \leq 1 \) at any selection \( x' = (\mu', \nu', p') \) of a maximum trade rule \( f \) at profile \( R \), the maximal utility that agent 3 can obtain at profile \( R \) equals \( \nu_{34} = 0 = 1 \).

Consider next the profile \( \tilde{R} \in \mathcal{R} \) where all agents except agent 3 have the same values as in profile \( R \), and:

\[
\tilde{v}_{3h} = (0, 0, -2, -2, -2),
\]

i.e., agent 3 misrepresents his values. Note first that \( |\nu''| \leq 3 \) for all \( x'' \in \mathcal{E}_{\tilde{R}} \). To see this, suppose that \( |\nu''| = 4 \) for some \( x'' \in \mathcal{E}_{\tilde{R}} \). By using the similar arguments as in the above, it must then be the case that \( \mu''_2 = 3, \mu''_3 = 1, \) and \( p''_1 = p''_3 = 0 \). But then agent 1 must be assigned house 2 or 4 and will, consequently, envy agents 2 and 3 at any feasible price vector. This contradicts that \( x'' \) is an equilibrium. Hence, \( |\nu''| \leq 3 \) for all \( x'' \in \mathcal{E}_{\tilde{R}} \).

We next remark that \( |\nu''| = 3 \) for any maximum trade rule \( f \) at profile \( \tilde{R} \). This follows directly as \( x'' = (\mu'', \nu'', p'') \) is an equilibrium state at profile \( \tilde{R} \) for \( \mu'' = (3, 2, 1, 4), \nu'' = (1, 0, 1, 1), \) and \( p'' = (0, 1, 0, 0) \).

The final part of the proof demonstrates that \( \mu''_2 = 1 \) and \( p''_3 = 0 \) for any selection \( x'' \) made by a maximum trade rule \( f \) at profile \( \tilde{R} \). This completes the proof of the proposition as the utility of agent 3 when misrepresenting and when reporting truthfully then equals \( u_{31}(p'') = 2 - 0 = 2 \) and (at most) \( v_{34} = 0 = 1 \), respectively. Suppose first that \( \mu''_3 \neq 1 \). Then it must be the case that \( \mu''_3 = 3 \) and \( \nu''_3 = 0 \) because if this is not the case, then agent 3 will envy the agent \( a \) with \( \mu''_a = 3 \) at any feasible price vector contradicting that \( x'' \) is an equilibrium. But if \( \mu''_3 = 3 \) and \( \nu''_3 = 0 \), it must be the case that \( \mu''_2 = 2 \) and \( \nu''_2 = 0 \) because if this is not the case, then agent 2 will envy the agent \( a \) with \( \mu''_a = 2 \) at any feasible price vector contradicting that \( x'' \) is an equilibrium. But if \( \nu''_2 = \nu''_2 = 0 \), then \( |\nu''| < 3 \) which contradicts that \( x'' \) is selected by a maximum trade rule \( f \). Hence, \( \mu''_2 = 1 \). But if \( \mu''_3 = 1 \), then it must be the case that \( p''_3 = 0 \) because if this not is the case, then agent 3 will envy the agent \( a \) with \( \mu''_a = 3 \) at any feasible price vector contradicting that \( x'' \) is an equilibrium. Hence, \( \mu''_3 = 1 \) and \( p''_3 = 0 \) as desired.

To prove the subsequent results, some consequences of the domain restriction (stated as lemmas) are derived for which some additional concepts are needed.

Let \( q > 1 \) and \( a_j \in A \) for \( 1 \leq j \leq q \). Given two assignments \( \mu \) and \( \mu' \), a trading cycle from \( \mu \) to \( \mu' \) is a sequence \( G = (a_1, \ldots, a_q) \) of distinct agents such that \( \mu'_{a_j} = \mu_{a_{j+1}} \), for \( 1 \leq j < q \) and \( \mu'_{a_q} = \mu_{a_1} \). For simplicity, we will use the same notation for the sequence
and by assumption, it follows that \(\mu\). Hence, \(\mu\).

Let \(R, R' \in \tilde{\mathcal{R}}\) be two profiles such that \(R' = (R_C, R_{-C})\) for some \(C \subseteq A\) (where possibly \(C = \emptyset\) and \(R = R'\)), and consider two equilibrium states \(x = (\mu, \nu, p) \in \mathcal{E}_R\) and \(x' = (\mu', \nu', p') \in \mathcal{E}_{R'}\) for all \(a \in C\). Let \(H_1, H_2, \) and \(H_3\) be defined as:

\[
\begin{align*}
H_1 &= \{h \in H : p'_h < p_h\}, \\
H_2 &= \{h \in H : p'_h = p_h\}, \\
H_3 &= \{h \in H : p'_h > p_h\}.
\end{align*}
\]

**Lemma 1.** Let \(R\) and \(R' = (R_C, R_{-C})\) be two profiles in \(\tilde{\mathcal{R}}\), and \(x = (\mu, \nu, p) \in \mathcal{E}_R\) and \(x' = (\mu', \nu', p') \in \mathcal{E}_{R'}\) be two equilibrium states. Let also \(G = (a_1, \ldots, a_q)\) be a trading cycle from \(\mu\) to \(\mu'\), and \((\mu_1, \ldots, \mu_q)\) the corresponding set of houses.

(i) If \(a_k \in G\) and \(x_{a_k} P_a x_{a_k}\), then \(\mu'_{a_k} \in H_1\).

(ii) If \(\mu_a \in H_1, \mu'_a \in H_2 \cup H_3\) and \(a \notin C\), then \(x_a = a, \mu'_a \in H_2, \) and \(x_a I_a x'_a\).

**Proof.** Part (i) of the lemma is proved by contradiction. Assume that \(a_k \in G\) and \(x_{a_k} P_a x_{a_k}\), but that \(\mu'_{a_k} \notin H_1\). Note first that \(\nu'_{a_k} = 1\). To see this, suppose that \(\nu'_{a_k} = 0\) or, equivalently, that \(x_{a_k} = a_k\). Because \(x\) is an equilibrium state, it must be the case that \(x_{a_k} R_a x_{a_k}\). But then \(x_{a_k} R_a x_{a_k}\), which contradicts the assumption that \(x_{a_k} P_a x_{a_k}\). Hence, \(\nu'_{a_k} = 1\). Note next that \(x_{a_k} R_a (\mu'_{a_k}, p)\) and \((\mu'_{a_k}, p) R_a (\mu'_{a_k}, p')\) because \(x\) is an equilibrium state and \(\mu'_{a_k} \notin H_1\), respectively. But then \(x_{a_k} R_a (\mu'_{a_k}, p')\). Now, \(x'_{a_k} = (\mu'_{a_k}, p')\) because \(\nu'_{a_k} = 1\). Consequently, \(x_{a_k} R_a x'_{a_k}\) which, again, contradicts the assumption that \(x_{a_k} P_a x_{a_k}\). Hence, \(\mu'_{a_k} \in H_1\).

To prove prove Part (ii) of the lemma, note that because \(\mu_a \in H_1\) and \(\mu'_a \in H_2 \cup H_3\), by assumption, it follows that \(\mu_a \neq \mu'_a\) and that agent \(a\) must belong to some trading cycle from \(\mu\) to \(\mu'\). Since \(a \notin C\) we have \(R'_a = R_a\). Thus, \(x_{a_k} R_a (\mu'_a, p) R_a x'_{a_k}\) as \(\mu'_a \in H_2 \cup H_3\) and \(x_{a_k} = (\mu'_a, p')\). Suppose that \(\mu'_a \in H_3\). If \(x_a = a\), then \(a R_a (\mu'_a, p) P_a x'_{a_k}\), which contradicts that \(x'\) is individual rational. If \(x_a \neq a\), then \(x_{a_k} P_a x'_{a_k}\), which is a contradiction to \(x' \in \mathcal{E}_{R'}\). Hence, \(\mu'_a \notin H_3\), i.e., \(\mu'_a \in H_2\). It now follows directly that if \(x_a = a\) then \(x_{a_k} I_a x'_{a_k}\), and if \(x_a \neq a\) then \((\mu_a, p') P_a x'_{a_k}\), which is a contradiction to \(x' \in \mathcal{E}_{R'}\). Hence, \(x_a = a, \mu'_a \in H_2,\) and \(x_{a_k} I_a x'_{a_k}\). \(\square\)

**Lemma 2.** Let \(R\) and \(R' = (R_C, R_{-C})\) be two profiles in \(\tilde{\mathcal{R}}\), and \(x = (\mu, \nu, p) \in \mathcal{E}_R\) and \(x' = (\mu', \nu', p') \in \mathcal{E}_{R'}\) be two equilibrium states where \(x_{a_k} P_a x_{a_k}\) for all \(a \in C\). Let also \(G = (a_1, \ldots, a_q)\) be a trading cycle from \(\mu\) to \(\mu'\), and \((\mu_1, \ldots, \mu_q)\) the corresponding set of houses. Then \(\mu_{a_k} \in H_1\) for some \(a_k \in G\) implies that \(\mu_{a_j} \notin H_3\) for all \(a_j \in G\).

**Proof.** For notational simplicity, let \(h_j = \mu_{a_j}\) for all \(1 \leq j \leq q\). To obtain a contradiction, suppose that \(h_k \in H_1\) but \(h_j \in H_3\) where, without loss of generality, \(k < l\). A first observation is that \(a_j \notin C\) for \(k \leq j < l\). This follows directly from Lemma 1(i) as \(\mu_{a_j} \in H_2 \cup H_3\) for all \(k \leq j < l\) by construction. Hence, \(R'_{a_j} = R_{a_j}\) for all \(k \leq j < l\). We will consider the cases when \(k + l = l\) and \(k + 1 < l\). By Lemma 1(ii), \(x_{a_k} = a_k = h_k\)
and \( h_{k+1} \in H_2 \), implying that \( k + 1 = l \) is impossible. Thus, in the latter case, we may suppose, without loss of generality, \( h_j \in H_2 \) for \( k < j < l \).

A second observation is that \( x'_{a_j} I_{x_{a_j}} \) for \( k \leq j < l \). For \( j = k \) this follows from Lemma 1(ii). For all \( k < j < l - 1 \), it follows from the facts that \( h_j, h_{j+1} \in H_2, R'_{a_j} = R_{a_j} \), and that \( x \) and \( x' \) are equilibrium states. For \( j = l - 1 \), we have \( a_{l-1} \notin C \), \( \mu_{a_{l-1}} \in H_2 \) and \( \mu'_{a_{l-1}} \in H_3 \). Applying Lemma 1(ii) to \( R' \) now yields \( x'_{a_{l-1}} = a_{l-1} \) and \( (h_{l-1}, p)l'_{a_{l-1}} = a_{l-1} \). Now, because \( k + 1 < l \) and both \( x_{a_k} = a_k \) and \( x'_{a_{l-1}} = a_{l-1} \), there exist \( l' \) and \( l'' \) where \( k \leq l' < l'' \leq l - 1 \) such that for all \( l' < j < l'' \) we have \( x_j \neq a_j \neq x'_{j} \) and both \( x_{a_{l''}} = a_{l''} \) and \( x'_{a_{l''}} = a_{l''} \). But then:

- \( a_{l''} = (h_{l''+1}, p), a_{l''} I_{a_{l''}}(h_{l''+1}, p) \) and \( R'_{a_{l''}} = R_{a_{l''}} \).
- \( (h_j, p)I_{a_j}(h_{j+1}, p) \) and \( R'_{a_j} = R_{a_j} \) for all \( l' < j < l'' \).
- \( (h_{l''}, p)I'_{a_{l''}}a_{l''} \) (where \( R'_{a_{l''}} = R_{a_{l''}} \) if \( l'' < l \)).

Now by (a)–(c), houses \( a_{l''} \) and \( a_{l''} \) are connected by indifference at profile \( R' \) which contradicts that the profile \( R' \) belongs to \( \mathcal{R} \).

An immediate consequence of Lemma 2 is that the set of trading cycles from \( \mu \) to \( \mu' \) can be partitioned into two disjoint groups as explained in the following definition.

**Definition 5.** Let \( R \) and \( R' = (R'_C, R'_C) \) be two profiles in \( \tilde{\mathcal{R}} \), and \( x = (\mu, \nu, p) \in \mathcal{E}_R \) and \( x' = (\mu', \nu', p') \in \mathcal{E}_{R'} \) be two equilibrium states where \( x'_a P_a x_a \) for all \( a \in C \). Let \( A^+ \subseteq A \) be such that \( a \in A^+ \) precisely when there is a trading cycle \( G \) from \( \mu \) to \( \mu' \) such that \( a \in G \) and \( \mu_a \in H_1 \) for some \( a' \in G \). Let \( A^- = A \setminus A^+ \).

The notations \( A^+ \) and \( A^- \) are chosen because all agents in \( A^+ \) are weakly better off at the equilibrium state \( x' \) than at the equilibrium state \( x \), while no agent in \( A^- \) is strictly better off at the equilibrium state \( x' \) than at the equilibrium state \( x \). This is demonstrated in the next lemma.

**Lemma 3.** Let \( R \) and \( R' = (R'_C, R'_C) \) be two profiles in \( \tilde{\mathcal{R}} \), and \( x = (\mu, \nu, p) \in \mathcal{E}_R \) and \( x' = (\mu', \nu', p') \in \mathcal{E}_{R'} \) be two equilibrium states where \( x'_a P_a x_a \) for all \( a \in C \). Let \( G \subseteq A \) be a trading cycle from \( \mu \) to \( \mu' \). If \( x'_a P_a x_a \) for some agent \( a \in G \), then \( G \subseteq A^+ \) and \( x'_a R_\hat{a} x_\hat{a} \) for all \( \hat{a} \in G \).

**Proof.** Note first that Lemma 1(i) implies that \( \mu'_a \in H_1 \) since \( x'_a P_a x_a \). Hence, \( G \subseteq A^+ \) and \( \mu_\hat{a} \in H_1 \cup H_2 \) for all \( \hat{a} \in G \) by Lemma 2 and by the fact that \( G \) is a trading cycle from \( \mu \) to \( \mu' \). Note next that either \( x'_a P_\hat{a} x_\hat{a} \) or \( x_\hat{a} R_\hat{a} x'_\hat{a} \) for all \( \hat{a} \in G \). In the latter case, \( \hat{a} \notin C \) and \( R'_\hat{a} = R_\hat{a} \). But then from \( \mu_\hat{a} \in H_1 \cup H_2 \) we obtain \( x'_a R_\hat{a}(\mu_\hat{a}, p')(R_\hat{a}(\mu_\hat{a}, p) \) because \( x' \) is an equilibrium state. If \( x_\hat{a} = (\mu_\hat{a}, p) \), then \( x'_\hat{a} R_\hat{a} x_\hat{a} \). Otherwise, \( x_\hat{a} = \hat{a} \) from the fact that \( x' \) is an equilibrium state, \( x'_\hat{a} R_\hat{a} \hat{a} \). Hence, \( x'_\hat{a} R_\hat{a} x_\hat{a} \) for all \( \hat{a} \in G \). 

**Theorem 1.** There is a unique minimum equilibrium price vector \( p^* \in \Pi_R \) for each profile \( R \in \mathcal{R} \).
Proof. Let \( R \in \overline{R} \), and let \( x' = (\mu', \nu', p') \in \mathcal{E}_R \) and \( x'' = (\mu'', \nu'', p'') \in \mathcal{E}_R \) be two equilibrium states. We will demonstrate that \( x = (\mu, \nu, p) \in \mathcal{E}_R \) for some assignments \( \mu \) and \( \nu \) if \( p_h = \min\{p'_h, p''_h\} \) for each \( h \in H \). The proof of the theorem then follows directly since the set \( \Pi_R \) is closed and bounded from below.

Consider the equilibrium states \( x' = (\mu', \nu', p') \) and \( x'' = (\mu'', \nu'', p'') \), and the trading cycles from \( \mu' \) to \( \mu'' \). Let the sets \( A^+ \) and \( A^- \) be defined as in Definition 5 with the restriction \( R = R' \), and define \( p_h = \min\{p'_h, p''_h\} \) for each \( h \in H \). Let:

\[
\mu_a = \begin{cases} 
\mu'_a & \text{if } a \in A^+, \\
\mu''_a & \text{if } a \in A^-.
\end{cases}
\]

Note that the assignment \( \mu \) defined in this way becomes bijective because no agent \( a \in A^+ \) belongs to a trading cycle containing an agent in \( A^- \) by Lemma 2. Let now \( x_a = x''_a \) and \( \nu_a = \nu''_a \) for all \( a \in A^+ \), and \( x_a = x'_a \) and \( \nu_a = \nu'_a \) for all \( a \in A^- \). To prove the theorem, we need to demonstrate that \( x = (\mu, \nu, p) \) is an equilibrium state. Now, the following is true for any \( a \in A^+ \) (recall that \( R = R' \)):

(a) \( x''_a R_a a \) because of individual rationality,

(b) \( x''_a R_a (h, p'') \) for all \( h \in H \) as \( x'' \) is an equilibrium state,

(c) \( x''_a R_a x'_a \) by Lemma 3 since \( a \in A^+ \),

(d) \( x''_a R_a (h, p') \) for all \( h \in H \) as \( x' \) is an equilibrium state.

From (a)–(d) in the above and the construction that \( x_a = x''_a \) and \( \nu_a = \nu''_a \) for all \( a \in A^+ \), it now follows that \( x_a R_a a \) and \( x_a R_a (h, p) \) for all \( a \in A^+ \) and all \( h \in H \). Symmetric arguments now give that \( x_a R_a a \) and \( x_a R_a (h, p) \) for all \( a \in A^- \) and all \( h \in H \). Hence, \( x = (\mu, \nu, p) \) is an equilibrium state if the assignment \( \nu \) implies maximal trade (see Definition 1). If this condition is not satisfied, it only remains to change the assignment \( \nu \) so trade becomes maximal. Hence, \( x = (\mu, \nu, p) \) is an equilibrium state.

**Proposition 5.** Let \( f \) be a minimum price mechanism with domain \( \overline{R} \). Then \( f \) is a maximum trade rule.

Proof. To obtain a contradiction, suppose that \( f \) is a minimum price mechanism but not a maximum trade rule. Let also the state \( x' = (\mu', \nu', p') \in \mathcal{E}_R \) be selected by the minimum price mechanism, i.e., \( p' \) is the unique minimum equilibrium price vector in \( \Pi_R \) by Theorem 1. From Theorem 1 and the assumption that \( f \) is not a maximum trade rule, it then follows that there is a state \( x = (\mu, \nu, p) \in \mathcal{E}_R \) where \( p' \neq p, p'_h \leq p_h \) for all \( h \in H \), and \( |\nu'| < |\nu| \).

Recall next that the complete trade from \( \mu \) to \( \mu' \) can be decomposed uniquely into a number of trading cycles. Because \( |\nu'| < |\nu| \), by assumption, this means that there must be a trading cycle \( G = (a_1, \ldots, a_q) \) from \( \mu \) to \( \mu' \) where \( \Sigma_{a \in G} \nu_a > \Sigma_{a \in G} \nu'_a \), and, consequently, an agent \( a_1 \in G \) with \( \mu'_{a_1} = a_1 \) and \( \nu'_{a_1} = 0 \). Note also that \( \mu_{a_j} \in H_1 \cup H_2 \) for all \( j \in G \) as \( p'_h \leq p_h \) for all \( h \in H \).
Let now agent $a_t \in G$ be defined as in the above, and let $a_j \in G$ for all indices $1 \leq j \leq q$. We will next demonstrate that $\mu_{a_t} \in H_2$ and $a_t I_{a_t}(\mu_{a_t}, p)$, as $\mu_{a_t} \in H_1 \cup H_2$, it suffices to show that $\mu_{a_t} \notin H_1$ to prove the first part of the statement. To obtain a contradiction, suppose that $\mu_{a_t} \in H_1$. Because $\mu_{a_t} \in H_1$, $\mu_{a_t} \neq a_t$, and $(\mu, \nu, p) \in \mathcal{E}_R$, it follows that:

$$(\mu_{a_t}, p') P_{a_t}(\mu_{a_t}, p) R_{a_t} a_t.$$ 

But then state $(\mu', \nu', p')$ cannot belong to $\mathcal{E}_R$ since $x_{a_t'} = a_t$. Hence, $\mu_{a_t} \in H_2$. But if $\mu_{a_t} \in H_2$ and $x_{a_t'} = a_t$, it is immediately clear that $x_{a_t'} I_{a_t} x_{a_t}$ as both $x$ and $x'$ belong to $\mathcal{E}_R$. Note that the latter condition may also be written as $a_t I_{a_t}(\mu_{a_t}, p)$ since $x_{a_t'} = a_t$.

Let again agent $a_t \in G$ be defined as in the above. Given the above findings, we next remark that either (i) $\mu_{a_t} \in H_2$ for all $k < j \leq l$ and $\mu_{a_k} \in H_1$ for some $a_k \in G$, or (ii) $\mu_{a_j} \in H_2$ for all $a_j \in G$. We will demonstrate that both these cases lead to the desired contradiction.

**Case (i).** Suppose first that $x_{a_k} \neq a_k$. Because $(\mu, \nu, p) \in \mathcal{E}_R$, $\mu_{a_k} \in H_1$, and $\mu_{a_k} = \mu_{a_{k+1}} \in H_2$ it follows that:

$$(\mu_{a_k}, p') P_{a_k}(\mu_{a_k}, p) R_{a_k} x_{a_k'},$$

which contradicts that $(\mu', \nu', p') \in \mathcal{E}_R$. Hence, $x_{a_k} \neq a_k$ cannot be the case. Suppose instead that $x_{a_k} = a_k$, and note that $x_{a_k} I_{a_k} x_{a_k'}$ for all $k \leq j \leq l - 1$. This follows as both $x$ and $x'$ belong to $\mathcal{E}_R$ and $\mu_{a_j} \in H_2$ for all $k < j \leq l$. But then houses $a_k$ and $a_l$ are connected by indifference at prices $p$ as $a_k I_{a_k}(a_{k+1}, p)$ and $a_l I_{a_l}(\mu_{a_l}, p)$. Hence, $x_{a_k} = a_k$ cannot be the case.

**Case (ii).** If $\mu_{a_j} \in H_2$ for all $a_j \in G$, it follows, by the same arguments as in Case (i), that $x_{a_j} I_{a_j} x_{a_j'}$ for all $a_j \in G$. Now, if $\mu_{a_j} = a_{l'}$ for some $a_{l'} \in G$ and $\mu_{a_j} \neq a_j$ for all $l' < j \leq l$, houses $a_{l'}$ and $a_j$ are connected by indifference at prices $p$ as $a_{l'} I_{a_{l'}}(a_{l'+1}, p)$ and $a_l I_{a_l}(\mu_{a_l}, p)$. On the other hand, if $\mu_{a_{l'}} \neq a_j$ for all $a_{l'} \in G$, then the trade at state $x'$ can be increased since $\mu_{a_{l'}} = a_l$ and $\nu_{a_{l'}} = 0$, which contradicts that $x' \in \mathcal{E}_R$.

The following lemma is the key in the proofs of Theorems 2 and 3.

**Lemma 4.** Let $R, R' \in \mathcal{R}$ be two profiles such that $R' = (R'_C, R'_C)$ for some $C \subset A$. Let also $x = (\mu, \nu, p) \in \mathcal{E}_R$ and $x' = (\mu', \nu', p') \in \mathcal{E}_{R'}$ be two equilibrium states such that $x_a P_a x_a$ for all $a \in C$. If $H_1 \neq \emptyset$, then there is a subset $S \subset H_1$ such that $A_S = \emptyset$ where:

$$A_S = \{a \in A : \mu_a \notin S \text{ and } x_a I_a(h, p) \text{ for some } h \in S\}.$$ 

**Proof.** Note first that it is safe to assume that $C = \{a \in A : x_a P_a x_a\}$ as $R'_a = R_a$ is an allowed report for all agents $a \in C$. To obtain a contradiction, suppose that $A_S \neq \emptyset$ for each $S \subset H_1$. Then there is a subset $S \subset H_1$ and an agent $a_0 \in A$ with $\mu_{a_0} \notin H_1$ and $x_{a_0} I_{a_0}(h, p)$ for some $h \in S$. Now, $x_{a_0} R_{a_0} a_0$ by individual rationality and $(h, p') P_{a_0}(h, p)$ as preferences are strictly monotonic and $p_{h'} > p_h$. Hence, $(h, p') P_{a_0}(h, p) I_{a_0} x_{a_0} R_{a_0} a_0$, and, obviously, $a_0 \in C$ and $\mu_{a_0} = (a_t, a_{t-1}, \ldots, a_1, a_0)$ from $\mu$ to $\mu'$. Since $\mu_{a_0} \in H_1$, it follows from Lemma 2 that $\mu_{a_j} \in H_1 \cup H_2$ for all $0 \leq j \leq t$,
and $\mu_{a_0} \in H_2$ because $\mu_{a_0} \notin H_1$. Let $0 < l \leq t$ be minimal such that $\mu_{a_l} \in H_1$, and note that such an index exists because $\mu_{a_{l-1}} \in H_1$. But then $\mu_{a_l} \in H_2$ and, consequently, $a_l \notin C$ by Lemma 1(i). Because $\mu_{a_l} \in H_1$ and $\mu_{a_l} \in H_2$, Lemma 1(ii) yields $x_{a_l} = a_l$ and $a_l I_{a_l}(\mu_{a_{l-1}}, p)$. Furthermore, for $0 < j < l$, we have $\mu_{a_j} \in H_2$, $a_j \notin C$, $x_{a_j} I_{a_j}(x'_{a_j})$ and $x'_{a_j} \neq a_j$ because $R$ belongs to $\tilde{R}$.

It is next established that $x_{a_j} P_{a_j}(a_l, p)$ for all $j \in \{a_0, a_1, \ldots, a_l\}$. To obtain a contradiction, suppose that $x_{a_0} I_{a_0}(a_l, p)$. Then it is possible to define an assignment $\mu^{\prime\prime}$ such that $\mu^{\prime\prime}_a = \mu_a$ for $a \in A\{a_0, a_1, \ldots, a_l\}$, $\mu^{\prime\prime}_{a_j} = \mu_{a_{j-1}}$ for $0 < j \leq l$, and $\mu^{\prime\prime}_{a_0} = a_l$. Further, let $\nu''_a = \nu_a$ for $a \in A\{a_0, a_1, \ldots, a_l\}$ and $\nu''_{a_0} = 1$ for $a \in \{a_0, a_1, \ldots, a_l\}$. Note that $\nu''_a = 1$ for $a \in \{a_0, a_1, \ldots, a_l\}$ is a utility maximizing choice for agent $a$ since for $a = a_j$, $x_{a_j} R_{a_j}(a, h, p)$ for all $h \in H$, $x_{a_j} I_{a_j}(\mu_{a_{j-1}}, p)$, and both $x'_{a_j} \neq a_j$ and $\nu''_{a_j} = 1$. Then the triple $(\mu'', \nu'', p)$ satisfies the requirements of Definition 1. However, by comparing $x'' = (\mu'', \nu'', p)$ and $x = (\mu, \nu, p)$, we see that trade is larger at $x''$ than at $x$, i.e, $\nu_{a_0} = 0$ while $\nu''_{a_0} = 1$. This contradicts that $x$ is an equilibrium state. Similar argument can be used to derive a contradiction if $x_{a_j} I_{a_j}(a_l, p)$ for some $0 < j < l$. Hence, $x_{a_j} P_{a_j}(a_l, p)$ for all $j \in \{a_0, a_1, \ldots, a_l\}$.

Recall next that $A_S \neq \emptyset$ for each $S \subset H_1$ by assumption. Then because $a_l \in H_1$, it follows that $A_{\{a_l\}} \neq \emptyset$. Let $\hat{a}_0 \in A_{\{a_l\}}$, and note that $\hat{a}_0 \notin \{a_0, a_1, \ldots, a_l\}$ as $x_{a_j} P_{a_j}(a_l, p)$ for all $0 \leq j < l$ by the above conclusion. Consider next the following two cases:

(I) Suppose that $\mu_{\hat{a}_0} \notin H_1$. Then, again, $\hat{a}_0$ belongs to some trading cycle $\hat{G} = (\hat{a}_l, \hat{a}_{l-1}, \ldots, \hat{a}_1, \hat{a}_0)$ from $\mu$ to $\mu'$. Again $\hat{a}_0 \in C$ and $\mu_{\hat{a}_0} \in H_2$, and there exists $0 < k \leq l$ such that $\mu_{\hat{a}_k} \in H_1$ and both $\mu_{\hat{a}_j} \in H_2$ and $x'_{a_j} \neq \hat{a}_j$ for all $0 < j < k$. Again $x_{\hat{a}_k} = \hat{a}_k$ and $\hat{a}_k I_{\hat{a}_k}(\mu'_{\hat{a}_k}, p)$. Because $G$ and $\hat{G}$ are trading cycles, we have $\hat{a}_j \notin \{a_0, a_1, \ldots, a_l\}$ for all $0 \leq j < k$. Now if (a) $\hat{a}_k = \mu'_{a_0}$ or (b) for some $0 \leq j < k$, $x_{a_j} I_{a_j}(\hat{a}_k, p)$ or (c) for some $0 \leq j \leq l$ and $0 \leq j' \leq k$, we have $x_{a_j} I_{a_j}(\mu_{\hat{a}_j}, p)$, then, in all cases (a), (b) and (c), we can construct similar as above from $x$ an equilibrium state $x''$ where trade is larger at $x''$ compared to $x$, which is a contradiction. Thus, suppose that (a), (b) and (c) are not true, in particular, $x_{a_j} P_{a_j}(\hat{a}_k, p)$ for all $0 \leq j \leq l$, and $x_{a_j} P_{a_j}(\hat{a}_k, p)$ for all $0 \leq j < k$. By $\hat{a}_k \in H_1$ and the above assumption that $A_S \neq \emptyset$ for each $S \subset H_1$, it then follows that $A_{\{\hat{a}_k\}} \neq \emptyset$. Let $a'_0 \in A_{\{\hat{a}_k\}}$. Now we have $a'_0 \notin \{\hat{a}_0, \hat{a}_1, \ldots, \hat{a}_k\} \cup \{a_0, a_1, \ldots, a_l\}$.

(II) Suppose that $\mu_{\hat{a}_0} \in H_1$. Now, if $x_{a_j} I_{a_j}(\mu_{\hat{a}_0}, p)$ for some $0 \leq j \leq l$, it is possible to construct, in a similar fashion as in the above, an equilibrium state $x''$ where trade is larger at $x''$ compared to $x$, which is a contradiction. Thus, $x_{a_j} P_{a_j}(\mu_{\hat{a}_0}, p)$ for all $0 \leq j \leq l$. By $\mu_{\hat{a}_0} \in H_1$ and the above assumption that $A_S \neq \emptyset$ for each $S \subset H_1$, it then follows that $A_{\{\mu_{\hat{a}_0}\}} \neq \emptyset$. Let $a'_0 \in A_{\{\mu_{\hat{a}_0}\}}$. Since $x_{a_j} P_{a_j}(\mu_{\hat{a}_0}, p)$ for all $0 \leq j \leq l$, we have $a'_0 \notin \{\hat{a}_0, a_0, a_1, \ldots, a_l\}$.

We next observe that if $\mu_{a_0} \notin H_1$, then as in (I) we can find another sequence $a'_0, a'_1, \ldots, a'_0$ where $x_{a'_0} = a_0 \in H_1$, $\mu_{a'_1} \in H_2$, $\mu_{a'_j} = \mu_{a'_{j-1}}$, $x'_{a'_j} \neq a'_j$ for $0 < j < o$, and $\mu_{a'_o} = \mu_{a_{o-1}}$, and otherwise as in (II) $\mu_{a'_{o}} \in H_1$. Then either we can use similar arguments as above to

23
From Lemma 4, it follows that there exists a nonempty set two equilibrium states such that then it is possible to decrease for all $a$

Suppose next, without loss of generality, that $H_1$ is finite. □

**Theorem 2.** Let $f$ be a minimum price mechanism with domain $\tilde{R}$. Then $f$ is group non-manipulable.

*Proof.* To obtain a contradiction, suppose that some nonempty group $C \subseteq A$ can manipulate the minimum price mechanism $f$ at a profile $R \in \tilde{R}$ by reporting preferences $R' = (R'_C, R_{-C}) \in \tilde{R}$. More precisely, let $x = (\mu, \nu, p) \in E_R$ and $x' = (\mu', \nu', p') \in E_{R'}$ be two equilibrium states such that $x'_aP_ax_a$ for all $a \in C$. As in the proof of Lemma 4, we will, without loss of generality, assume that $C = \{a \in A : x'_aP_ax_a\}$. Then $\mu'_a \in H_1$ for all $a \in C$ by Lemma 1(i) as $x'_aP_ax_a$ for all $a \in C$ and $C \neq \emptyset$. Hence, $H_1 \neq \emptyset$ and $p_h > y'_h \geq p_h$ for all $h \in H_1$. Let now:

$$A_S = \{a \in A : \mu_a \notin S \text{ and } x_aI_a(h, p) \text{ for some } h \in S\}.$$ 

From Lemma 4, it follows that there exists a nonempty set $S \subseteq H_1$ such that $A_S = \emptyset$. But then it is possible to decrease $p_h$ for all $h \in S$ (since $p_h > y'_h \geq p_h$ for all $h \in S$) and obtain a new equilibrium state by the Perturbation Lemma in Alkan et al. (1991) which contradicts that state $x$ is selected by $f$ at profile $R$. Hence, $f$ is group non-manipulable. □

**Proposition 3.** A minimum price mechanism $f$ is non-manipulable on the domain $R$ if and only if $1 \leq |A| \leq 3$.

*Proof.* We first prove that a minimum price mechanism is non-manipulable if $1 \leq |A| \leq 3$. We will, however, only prove the result for $|A| = 3$ as the proof for $1 \leq |A| \leq 2$ is a special case of the proof for $|A| = 3$. To obtain a contradiction, suppose that $|A| = 3$ and that some nonempty group $C \subseteq A$ can manipulate a minimum price mechanism $f$ at a profile $R \in \tilde{R}$ by reporting preferences $R' = (R'_C, R_{-C}) \in \tilde{R}$. Let also $x = (\mu, \nu, p)$ and $x' = (\mu', \nu', p')$ represent the selections of $f$ at profiles $R$ and $R'$, respectively. As in the proof of Lemma 4, we will, without loss of generality, assume that $C = \{a \in A : x'_aP_ax_a\}$. Note also that $\mu'_a \in H_1$ for all $a \in C$ by Lemma 1(i) as $x'_aP_ax_a$ for all $a \in C$.

We need to demonstrate that $|H_1| = 3$. The conclusion then follows by the Perturbation Lemma in Alkan et al. (1991) in the same fashion as in the proof of Theorem 2. Note first that $|H_1| \geq 1$, by the above observation, as $C \neq \emptyset$. To obtain a contradiction to $|H_1| = 3$, suppose that $|H_1| = 2$. This also means that there is an agent $a \in A$ with $\mu'_a \notin H_1$. Suppose next, without loss of generality, that $a = 3$, and note that $3 \notin C$. If $\mu_3 = \mu'_3$, then it must be the case that $x_3P_3(\mu_j, p)$ for $j = 1, 2$, otherwise $x'$ cannot be an equilibrium since $\mu_j \in H_1$ for $j = 1, 2$. But in this case, it is possible to decrease the prices of houses $\mu_1 \in H_1$ and $\mu_2 \in H_1$ at state $x$, by the Perturbation Lemma in Alkan et al. (1991), and obtain a new equilibrium which contradicts that $p$ is a minimum equilibrium price vector at profile $R$. Hence, $\mu_3 \neq \mu'_3$, and consequently, $\mu_3 \in H_1$ as $\mu'_3 \notin H_1$ and $|H_2| = 2$. But
this also means that $\mu_3 = 3$, $\mu'_3 \in H_2$, and $x_3I_3(\mu'_3, p)$, otherwise, state $x'$ cannot be an equilibrium as $\mu_3 \in H_1$.

Suppose next, without loss of generality, that $\mu'_3 = 2$, i.e., that $1, 3 \in H_1$. Hence, $x_3I_3(2, p)$, by the above conclusion, and $x_3I_3(1, p)$ otherwise $x'$ cannot be an equilibrium at profile $R$ as $1 \in H_1$. But then it must be the case that $x_jI_j(1, p_1)$ for the agent $j \neq 3$ with $\mu_j \neq 1$ otherwise it is possible to decrease $p_1 \in H_1$ and obtain a new equilibrium which contradicts that $p$ is a minimum equilibrium price vector at profile $R$. By identical arguments, it must also be the case that $x_kI_3(3, p_3)$ some agent $k \neq 3$. If $\mu_k = 2$, agents $k$ and $3$ can swap houses at allocation $x$ and a new equilibrium is obtained, but it is also possible to decrease the prices of all houses but 2 and obtain a new equilibrium, by the Perturbation Lemma in Alkan et al. (1991), which contradicts that $p$ is a minimum equilibrium price vector at profile $R$. If $\mu_k = 1$, a new equilibrium can be obtained at prices $p$ and for $\mu''_j = 1$, $\mu''_k = 3$, and $\mu''_3 = 2$, and it is again possible to decrease the prices of all houses but 2 to obtain a new equilibrium at profile $R$. Hence, in both cases it is possible to obtain a contradiction to $|A| = 2$. Hence, $|H_1| = 3$ as desired.

We next prove that a minimum price mechanism $f$ is non-manipulable on the domain $\mathcal{R}$ only if $1 \leq |A| \leq 3$, i.e., that $f$ can be manipulated by some agent, at some profile $R \in \mathcal{R}$, whenever $|A| > 3$. The proof is based on Example 2, and by using the same arguments as in the proof of Proposition 2, it is sufficient to demonstrate the result for $|A| = 3$.

Consider now the state $\hat{x} = (\hat{\mu}, \hat{\nu}, \hat{p}) \in \mathcal{E}_R$ and suppose that $\hat{p}$ is a minimum equilibrium price vector. We first demonstrate that $\hat{p} = p'$ or $\hat{p} = p''$. From Example 2, it is clear that either $\hat{p}_1 < 1$ or $\hat{p}_2 < 1$ as $\hat{p}$ is a minimum equilibrium price vector. Suppose that $\hat{p}_1 < 1$. Then $\hat{\mu}_3 = 1$ by envy-freeness as $\hat{x}$ is an equilibrium. Consequently, $\hat{\mu}_1 = 3$, $\hat{p}_3 = 0$ by individual rationality for agent 1, and it then follows that $\hat{\mu}_2 = 2$ by individual rationality for agent 2. But then it must be the case that $\hat{\mu}_4 = 4$ and $\hat{p}_2 \geq 1$ because otherwise agent 4 will envy agent 2 at state $\hat{x}$. Hence, $\hat{p} \geq p''$. But then $\hat{p} = p''$, by definition, as $\hat{p}$ is a minimum equilibrium price vector by assumption. Analogous arguments can be used to show that $\hat{p} = p'$ if $\hat{p}_2 < 1$.

Let now $f$ be minimum price mechanism on domain $\mathcal{R}$. Then $f$ chooses either $p'$ or $p''$. If $f$ chooses $p'$, then agent 3’s utility is equal to $v_{34} - p'_4 = 1$. Let $R'$ denote the profile of quasi-linear preferences where the entry $v_{32}$ in the matrix $V$ from Example 2 is replaced by $v'_{32} = 2$. Obviously, $x' \notin \mathcal{E}_{R'}$ because $(2, p'_3)P'_3x'$. On the other hand, it is easy to check that $x'' \in \mathcal{E}_{R'}$. Also, $p''$ is the unique minimum equilibrium price vector at profile $R'$. To see this, suppose that $\hat{x} = (\hat{\mu}, \hat{\nu}, \hat{p}) \in \mathcal{E}_{R'}$ and that $\hat{p} \neq p''$ is a minimum equilibrium price vector at profile $R'$. Then $\hat{p}_2 < 1$, which implies that $\hat{\mu}_4 = 2$ and $\hat{\mu}_3 = 1$. But then individual rationality cannot be satisfied for both agents 1 and 2 at state $x''$. Thus, $p''$ must be chosen by $f$ for profile $R'$. Then, by individual rationality for agents 1 and 2, it follows that agent 3 must receive house 1. Because $R' = (R'_3, R_{-3})$ and agent 3’s utility from $(1, p'')$ under $R_3$ is equal to $v_{31} - p''_1 = 2 > 1$, agent 3 can profitably manipulate $f$ at $R$.

If $f$ chooses $p''$, it can be shown, by identical arguments as in the above, that agent 4 can manipulate the rule by replacing the entry $v_{41}$ in the matrix $V$ from Example 2 is by $v'_{41} = 2$. 

\[\blacksquare\]
Proposition 6. For any given profile \( R \in \mathcal{R} \), a Dutch price sequence \((p^t)_{t=1}^\infty\) contains a finite number of price vectors, i.e., \( T < \infty \).

Proof. To obtain a contradiction, suppose that \((p^t)_{t=1}^\infty\) is a Dutch price sequence with \( T = \infty \). Let also \((x^t)_{t=1}^\infty\) be a supporting sequence of equilibrium states, where \( x^t = (\mu^t, \nu^t, p^t) \). Because there is only a finite number of assignments, there is an infinite subsequence \((t_j)_{j=1}^\infty\) of steps such that for some finite number \( j \) and some assignments \( \mu^j \) and \( \nu^j \), it holds that \( \mu^j = \mu^j \) and \( \nu^j = \nu^j \) for all \( j \geq j' \). Let also \( p^t \to p^e \) as \( t \to \infty \). We will demonstrate that \( p^e \in \Pi' \), which contradicts that \( T = \infty \) since \( \nu^{j'} = \nu' \).

Consider now the states \( x^{j'} = (\mu^{j'}, \nu^{j'}, p^{j'}) = (\mu^j, \nu^j, p^j) \) for all \( j \geq j' \). Because \( x^{j'} \in \mathcal{E} \), the following holds for all \( a \in A \):

\[
x^{j'}_a R_a a \text{ and } x^{j'}_a R_a (h, p^j) \text{ for all } j \geq j' \text{ and for all } h \in H.
\]

Moreover, by continuity, the following holds for all \( a \in A \):

\[
(\mu^j, \nu^j, p^e) R_a a \text{ and } (\mu^j, \nu^j, p^e) R_a (h, p^j) \text{ for all } h \in H.
\]

But then \( p^e \in \Pi' \). \( \square \)

Theorem 3. For any given profile \( R \in \tilde{\mathcal{R}} \), a Dutch price sequence \((p^t)_{t=1}^\infty\) is unique and \( p^T \) is the unique minimum equilibrium price vector in \( \Pi_R \).

Proof. We first prove that a Dutch price sequence is unique. To do this, consider the profile \( R \in \tilde{\mathcal{R}} \), and let \( x' = (\mu', \nu', p') \in \mathcal{E}_R \) and \( x'' = (\mu'', \nu'', p'') \in \mathcal{E}_R \) be two equilibrium states with a common price vector \( p \) (recall from Theorem 1 that the minimum price vector is unique on the domain \( \mathcal{R} \)). We need to demonstrate that \( \nu' = \nu'' \) to complete the proof. To see this, consider the correspondence \( \xi \) from the definition of a Dutch price sequence. If \( \nu' = \nu'' \), then there is just one state in \( \xi(p) \). This also means that, for a given profile \( R \in \tilde{\mathcal{R}} \), there is just one Dutch price sequence.

Suppose now that \( \nu' \neq \nu'' \), and consider a trading cycle \( G = (a_1, \ldots, a_q) \) from \( \mu' \) to \( \mu'' \) such that \( \nu'_{a_1} = 0 \). Such a trading cycle exists since \( \nu' \neq \nu'' \) by assumption. For each agent \( a_j \) in the trading cycle \( G \), let \( r_j = (\nu'_{a_j}, \nu''_{a_j}) \). Then \( r_j \) is equal to \( (0, 1) \), \((1, 1)\) or \( (0, 1) \), but not \( (0, 0) \) as agent \( a_j \) is included in \( G \). Moreover, \( r_1 = (0, 1) \) by assumption. Consider then the sequences \((r_l, r_{l+1}, \ldots, r_{q'})\) for \( 1 \leq l \leq q' \leq q \). Assume first that \( r_j \neq (1, 0) \) for all \( j \), i.e., that \( r_j = (0, 1) \) or \( r_j = (1, 1) \) for all \( j \). This means that trade is not maximal at the state \( x'' \). Note also that \( x'_a I_{a_j} x''_a \) for all \( j \) since prices are the same at the two states \( x' \) and \( x'' \). Hence, there must be a \( q' \) such that \( r_{q'} = (1, 0) \). But since \( r_1 = (0, 1) \), there must also be an \( l \) such that \( r_l = (0, 1) \) and \( r_j = (1, 1) \) for \( l < j < q' \). In that case, houses \( \mu'_{a_l} \) and \( \mu''_{a_l} \) are connected by indifference, contradicting our assumption that \( R \in \tilde{\mathcal{R}} \). Hence, \( \nu' = \nu'' \) must be the case, and, consequently, a Dutch price sequence is unique.

We next prove that \( p^T \) is the unique minimum equilibrium price vector \( p^* \) in \( \Pi_R \). From the first part of this theorem and Proposition 6 we know that a Dutch price sequence is unique and finite. Suppose that it converges to the price vector \( p^e \), but that \( p^* \leq p^e \) and \( p^* \neq p^e \). Let \( x^e = (\mu^e, \nu^e, p^e) \) and \( x^* = (\mu^*, \nu^*, p^*) \) be two corresponding equilibrium
states in $\mathcal{E}_R$. Then $H_1 \neq \emptyset$, so $A(S) = \emptyset$ for some $S \subset H_1$ by Lemma 4. Note also that $S \neq \emptyset$ and $p^e \in \Pi^e$. Consider now the set of houses $S$ and the set of agents $\hat{A}$ that are assigned houses in $S$, i.e., $\hat{A} = \{a \in A : \mu_a \in S\}$. Let also $A^0 = \{A \in \hat{A} : \nu^e = 0\}$ and $A^1 = \{A \in \hat{A} : \nu^e = 1\}$.

Since $p^* \leq p^e$ and $p^* \neq p^e$, for each $\varepsilon > 0$, there is a state $x^e = (\mu^e, \nu^e, p^e) \in \mathcal{E}_R$ such that $p^m \leq p^e$, $p^m \neq p^e$. Moreover, since $A(S) = \emptyset$, $x^e = x^e$ can be chosen for $a \in A \setminus \hat{A}$ for “sufficiently small” $\varepsilon$. Since there is only a finite number of assignments $\nu$, there is an infinite and increasing sequence $(\varepsilon_j)_{j=1}^{\infty}$ such that $\nu^{e_j} = \nu^e$ is constant for all $j$, and $\varepsilon_j \to 0$ as $j \to \infty$. Hence, $x^{e_j} = (\mu^{e_j}, \nu^{e_j}, p^{e_j})$. But then $x^* = (\mu^e, \nu^e, p^e) \in \xi(x^{T-1})$ for some $\mu^e$ by continuity of preferences. But then there is a $p \in \Pi^e$ such that $p \leq p^e$, $p \neq p^e$. This means that the Dutch price sequence cannot stop at $T$, which contradicts our assumptions. Hence, $p^e = p^*$ must be the case. \hfill $\Box$

**Proposition 7** For any profile $R \in \mathcal{R}$, the minimum price mechanism generates a weakly higher revenue to the public authority compared to the current U.K. system.

**Proof.** The current U.K. system can, for any profile $R \in \mathcal{R}$, be represented by a state $x = (\mu, \nu, p)$ where $p_h = \infty$ for all $h \in H$ as the interpretation of this situation, due to the assumption that each house in $H$ is bounded desirable, is that each tenant $a \in A$ is given a take-it-or-leave-it offer either to buy house $h = a$ at price $p_h = p_h$, or to continue renting house $h = a$.

Suppose now that the state $x' = (\mu', \nu', p')$ is selected by the minimum price mechanism at profile $R \in \mathcal{R}$. Note first that if $\nu_a = 1$, then $\nu'_a = 1$. This follows trivially because if $\nu_a = 1$ but $\nu'_a = 0$, then $(a, p_a)R_a a$ and $aP_a(a, p_a)$, respectively, which is a logical contradiction. This also means that all agents $a \in A$ that buy a house at state $x$ also buy a house at state $x'$. Furthermore, all agents that buy a house at state $x$ belong to one of the following two sets:

$$S = \{a \in A : \mu_a = \mu'_a \text{ and } \nu_a = 1\},$$

$$T = \{a \in A : \mu_a \neq \mu'_a \text{ and } \nu_a = 1\}.$$

It is clear that the revenue for the public authority from the sales to the agents in $S$ is identical at states $x'$ and $x$ since $\mu_a = a$ in this case. However, because each agent in $T$ must be involved in a trading cycle and $p' \geq p$, it is clear that the revenue for the public authority from the sales to the agents in $T$ is weakly higher at state $x'$ than at state $x$. This also proves the statement. (Note also that there may be agents $a \in A$ with $\nu_a = 0$ but $\nu'_a = 1$. This will further increase the revenue for the public authority by switching from state $x$ to state $x'$.) \hfill $\Box$
